The Institute for the Study of Labor (IZA) in Bonn is a local and virtual international research center and a place of communication between science, politics and business. IZA is an independent nonprofit organization supported by Deutsche Post Foundation. The center is associated with the University of Bonn and offers a stimulating research environment through its international network, workshops and conferences, data service, project support, research visits and doctoral program. IZA engages in (i) original and internationally competitive research in all fields of labor economics, (ii) development of policy concepts, and (iii) dissemination of research results and concepts to the interested public.

IZA Discussion Papers often represent preliminary work and are circulated to encourage discussion. Citation of such a paper should account for its provisional character. A revised version may be available directly from the author.

## ABSTRACT

### **How Fast Do Wages Adjust to Human-Capital Productivity? Dynamic Panel-Data Evidence from Belgium, Denmark and Finland\***

The standard human-capital model is based on the assumption that the observed wage of an individual is equal to the monetary value of the individual net human-capital productivity, the so-called net potential wage. We argue that this assumption is rejected by the ECHP data for Belgium, Denmark and Finland. The empirical evidence supports a dynamic approach to the Mincer equation where no equality is imposed but an adjustment between observed and potential earnings is allowed to take place over time. Controlling for regressors' endogeneity, individual heterogeneity and time effects, we estimate a dynamic panel-data wage equation and provide measures of the speed of adjustment in Belgium, Denmark and Finland. Further, we elaborate on the implications of a dynamic approach to the Mincer equation for the computation of the return to schooling, including the implication that this return is not independent of labor-market experience, as suggested by Heckman et al. (2005) and Belzil (2007). Finally, we show that a dynamic wage equation can be seen as the solution of a simple wage-bargaining model and argue that a micro-founded model can fit the data better than a simple adjustment model but requires more theoretical assumptions.

## 1. Introduction

In the standard human-capital model proposed by Mincer (1974), the logarithm of the hourly observed earnings of an individual is explained by schooling years, potential labor-market experience and experience squared. This section presents the theoretical foundations of the standard Mincerian equation as reported by Heckman et al. (2003). Therefore, we make no claim of originality at this stage and mainly aim at helping the reader with notations and terminology adopted in the next sections.

Mincer argues that potential earnings today depend on investments in human capital made yesterday. Denoting potential earnings at time  $t$  as  $E_t$ , Mincer assumes that an individual invests in human capital a share  $k_t$  of his potential earnings with a return of  $r_t$  in each period  $t$ . Therefore we have:

$$(1) \quad E_{t+1} = E_t(1 + r_t k_t)$$

which, after repeated substitution, becomes:

$$(2) \quad E_t = \prod_{j=0}^{t-1} (1 + r_j k_j) E_0$$

or alternatively:

$$(3) \quad \ln E_t = \ln E_0 + \sum_{j=0}^{t-1} \ln(1 + r_j k_j).$$

Under the assumptions that:

- schooling is the number of years  $s$  spent in full-time investment ( $k_0 = \dots = k_{s-1} = 1$ ),
- the return to schooling in terms of potential earnings is constant over time ( $r_0 = \dots = r_{s-1} = \beta$ ),
- the return to the post-schooling investment in terms of potential earnings is constant over time ( $r_s = \dots = r_{t-1} = \lambda$ ),

we can write expression (3) in the following manner:

$$(4) \quad \ln E_t = \ln E_0 + s \ln(1 + \beta) + \sum_{j=s}^{t-1} \ln(1 + \lambda k_j)$$

which yields:

$$(5) \quad \ln E_t \approx \ln E_0 + \beta s + \lambda \sum_{j=s}^{t-1} k_j$$

for small values of  $\beta$ ,  $\lambda$  and  $k$ <sup>1</sup>.

In order to build up a link between potential earnings and labor-market experience  $z$ , Mincer assumes that the post-schooling investment linearly decreases over time, that is:

$$(6) \quad k_{s+z} = \eta \left( 1 - \frac{z}{T} \right)$$

where  $z = t - s \geq 0$ ,  $T$  is the last year of the working life and  $\eta \in (0,1)$ .

Therefore, using (6), we can re-arrange expression (5) and get:

$$(7) \quad \ln E_t \approx \ln E_0 - \eta\lambda + \beta s + \left( \eta\lambda + \frac{\eta\lambda}{2T} \right) z - \left( \frac{\eta\lambda}{2T} \right) z^2.$$

Then, by subtracting (6) from (7), we obtain an expression for net potential earnings, i.e. potential earnings net of post-schooling investment costs:

$$(8) \quad \ln E_t - \eta \left( 1 - \frac{z}{T} \right) \approx \ln E_0 - \eta\lambda - \eta + \beta s + \left( \eta\lambda + \frac{\eta\lambda}{2T} + \frac{\eta}{T} \right) z - \left( \frac{\eta\lambda}{2T} \right) z^2$$

which can also be written as:

$$(9) \quad \ln npe_t \approx \alpha + \beta s + \delta z + \phi z^2$$

where  $\ln npe_t = \ln E_t - \eta \left( 1 - \frac{z}{T} \right)$ ,  $\alpha = \ln E_0 - \eta\lambda - \eta$ ,  $\delta = \eta\lambda + \frac{\eta\lambda}{2T} + \frac{\eta}{T}$  and  $\phi = -\frac{\eta\lambda}{2T}$ .

Finally, assuming that observed earnings are equal to net potential earnings at any time  $t$  (a key-assumption, as we will argue in the next section):

$$(10) \quad \ln w_t = \ln npe_t$$

and, using expression (9), we get the standard Mincer equation:

$$(11) \quad \ln w_t \approx \alpha + \beta s + \delta z + \phi z^2.$$

The remainder of this paper is as follows. Section 2 presents a dynamic adjustment model where assumption (10) is relaxed. Section 3 discusses the implications of the adjustment model for the computation of wage return to schooling. Section 4 shows that a dynamic wage equation can be seen as the solution of a simple wage-bargaining model. Section 5 summarizes the main results of the paper in the light of the existing literature on human-capital regressions.

## 2. Adjustment model

Following Heckman et al. (2003), the standard Mincerian framework seems to be characterized by two main features. First, it provides an explanation why the logarithm of the net potential earnings of an individual at time  $t = s + z$  can be approximately

---

<sup>1</sup> Note that the symbol of equality (=) in expression (4) becomes a symbol of rough equality ( $\approx$ ) in expression (5). It happens because, if  $x$  is closed to zero, then  $\ln(1+x) \approx x$ .

represented as a function of  $s$  and  $z$ , i.e. expression (9). Second, it is based on the *assumption* that, at any time  $t \geq s$ , the logarithm of the observed wage of an individual is equal to the monetary value of his net human-capital productivity, measured by his net potential wage, i.e. assumption (10).

This paper does not question expression (9) and focuses on assumption (10). On the lines of Flannery and Rangan (2006), we argue that assumption (10) can be replaced by a more flexible assumption. Particularly, observed earnings can be seen as dynamically adjusting to net potential earnings, according to the following simple adjustment model:

$$(12) \quad \ln w_t - \ln w_{t-1} = \rho(\ln npe_t - \ln w_{t-1})$$

where  $\rho \in [0,1]$  measures the speed of adjustment.

If  $\rho=1$ , then assumption (10) holds, observed earnings are equal (adjust) to net potential earnings at time  $t$  (within period  $t$ ), and the standard Mincerian model (11) holds. If instead  $\rho=0$ , then observed earnings are constant over time, always equal to the labor-market entry earnings  $\ln w_s$ , and do not adjust at all to variations of net potential earnings. In general, when the speed of adjustment is neither zero nor one, replacing expression (9) into (12) gives:

$$(13) \quad \ln w_t \approx (1-\rho)\ln w_{t-1} + \rho(\alpha + \beta s + \delta z + \phi z^2)$$

or alternatively:

$$(14) \quad \ln w_t \approx v_0 + v_1 \ln w_{t-1} + v_2 s + v_3 z + v_4 z^2$$

where  $v_0 = \rho\alpha$ ,  $v_1 = 1-\rho$ ,  $v_2 = \rho\beta$ ,  $v_3 = \rho\delta$  and  $v_4 = \rho\phi$ .

Expression (14) is a dynamic version of the Mincer equation, which we label adjustment model. Note that, when individual-level *longitudinal* data are available, the complement to one of the speed of adjustment ( $1-\rho$ ) can be estimated and the theory underlying (14) can be tested. The main requirement for the theory to be consistent with the data is to find that the coefficient  $v_1$  is significantly different from zero.

Table 1 presents estimates based on model (14). We use OLS and GMM techniques to explore data on male workers (we restrict to males in order to minimize sample-selection problems), aged between 18 and 65, from the European Community Household Panel for Belgium, Denmark and Finland. The Appendix contains a detailed description of the sample statistics and describes how the variables of model (14) are obtained from the original ECHP variables.

Our preferred estimates in Table 1 are the GMM-SYS estimates, accounting for the endogeneity, individual heterogeneity and time effects (Blundell and Bond, 1998). In our preferred estimates, the coefficient  $v_1 = 1-\rho$  is statistically different from zero and estimated at 0.218, 0.335 and 0.420 in Finland, Belgium and Denmark, respectively. This implies that the speed of adjustment  $\rho$  is statistically different from one and estimated at 0.782, 0.665 and 0.580 in Finland, Belgium and Denmark, respectively. So, the main empirical result is that the observed wage at time  $t$  is not equal (does not adjust) to the monetary value of the individual net human-capital productivity (the net potential wage) at time  $t$  (within period  $t$ ) since no country has a speed of adjustment either equal or closed to one. Hence, assumption (10) in the standard Mincerian model is rejected by the ECHP data for Belgium, Denmark and Finland.

Note that all standard tests are passed, *although* it is likely that extended versions of the adjustment model, with additional covariates, would probably fit the data better than the simple model (14). As expected, the OLS estimator over-estimates the autoregressive coefficient while the GMM-SYS estimates without year effects are not reliable because the corresponding model that does not pass the Hansen J over-identification test (Finland) or the Arellano-Bond 2<sup>nd</sup> order autocorrelation test<sup>2</sup> (Denmark), or both (Belgium).

As one would reasonably expect, due to different labor-market institutions, the speed of adjustment of observed hourly wages to human-capital productivity is heterogeneous across the three European countries considered in this study. Particularly, Finland is the country with the highest speed of adjustment, while Denmark is the country with the lowest speed.

The next section analyses the implications for the computation of the return to schooling deriving from the adoption of a dynamic approach to the Mincer equation. However, before closing this section, we would like to stress that model (14) has an additional interesting feature which will not be further explored in this paper. Particularly, it can be used to further justify some macroeconomic studies estimating the impact of schooling on GDP growth<sup>3</sup> and some microeconomic studies that estimate the impact of human capital on wage growth<sup>4</sup>. Indeed, by subtracting  $\ln w_{t-1}$  at both sides of expression (14), we get a version of model (14) where schooling and labor-market experience affect wage growth, namely  $\ln w_t - \ln w_{t-1} \approx \upsilon_0 - \rho \ln w_{t-1} + \upsilon_2 s + \upsilon_3 z + \upsilon_4 z^2$ .

### 3. Implications for the return to schooling

This section shows that a dynamic version of the Mincer equation implies that the return to schooling in terms of observed earnings is not independent of labor-market experience. This result is consistent with the empirical evidence provided by Heckman et. al. (2005) and Belzil (2007). In addition, it is shown that the return to schooling in terms of net potential earnings, provided by the standard Mincer equation, can also be computed using its dynamic version.

#### 3.1 Static return to schooling in terms of net potential earnings

To begin, we find of interest stressing that the total return to schooling in the static model (11) is given by the following expression:

$$(15) \quad \frac{\partial \ln w_t}{\partial s} = \frac{\partial \ln w_{s+z}}{\partial s} \approx \beta$$

and is constant over the working life, meaning independent of labor-market experience  $z$ . Further, because of assumption (10), the return to schooling in terms of observed earnings and the one in terms of net potential earnings coincide<sup>5</sup>.

---

<sup>2</sup> This test has been introduced by Arellano and Bond (1991).

<sup>3</sup> See Krueger and Lindahl (2001) for a review.

<sup>4</sup> See Rubinstein and Weiss (2006) for a review. Another interesting contribution on this issue is provided by Connolly and Gottschalk (2006).

<sup>5</sup> See expression (9).

We label  $\beta$  as static return to schooling in terms of net potential earnings and show, in subsection 3.3, that our interpretation of  $\beta$  in terms of *net potential* rather than *observed* earnings is the most appropriate.

### 3.2 Returns to schooling in terms of observed earnings

The dynamic model (14) allows obtaining the evolution of the schooling return over the entire working life. For instance, at time  $s$ , expression (14) can be written as follows:

$$(16) \quad \ln w_s \approx \rho\alpha + (1-\rho)\ln \bar{w}_{s-1} + \rho\beta s + \rho\delta 0 + \rho\phi 0^2$$

where  $\bar{w}_{s-1}$  is the minimum wage<sup>6</sup> at time  $s-1$ , assumed to be independent of schooling years. Therefore, the return to schooling at time  $s$ , i.e. when an individual enters the labor market, is given by:

$$(17) \quad \beta(0) = \frac{\partial \ln w_s}{\partial s} \approx \rho\beta.$$

Analogously, at time  $s+1$ , expression (14) can be written as follows:

$$(18) \quad \ln w_{s+1} \approx \rho\alpha + (1-\rho)\ln w_s + \rho\beta s + \rho\delta 1 + \rho\phi 1^2$$

and the total return to schooling is given by:

$$(19) \quad \beta(1) = \frac{\partial \ln w_{s+1}}{\partial s} \approx \rho\beta + \rho\beta(1-\rho).$$

At time  $s+2$ , expression (14) is as follows:

$$(20) \quad \ln w_{s+2} \approx \rho\alpha + (1-\rho)\ln w_{s+1} + \rho\beta s + \rho\delta 2 + \rho\phi 2^2$$

and the total return to schooling is given by:

$$(21) \quad \beta(2) = \frac{\partial \ln w_{s+2}}{\partial s} \approx \rho\beta + \rho\beta(1-\rho) + \rho\beta(1-\rho)^2.$$

Therefore, at time  $s+z$ , the return to schooling in terms of observed earnings is given by the following expression:

$$(22) \quad \beta(z) = \frac{\partial \ln w_{s+z}}{\partial s} \approx \rho\beta \left[ 1 + (1-\rho) + (1-\rho)^2 + (1-\rho)^3 + \dots + (1-\rho)^z \right],$$

---

<sup>6</sup> If current observed earnings depend on both past observed earnings and current net potential earnings, as suggested by model (14), it is easy to see that, at time  $s$ , i.e. at labor-market entry, the reference past wage for the representative individual cannot be the wage at time  $s-1$  because this wage is not observed (the individual is still enrolled in school at time  $s-1$ ). Therefore, we find reasonable to assume that, for an individual at labor-market entry, the reference past wage is the minimum wage at time  $s-1$ . So, at time  $s$ , the individual tries to obtain a salary that is above the minimum wage as a reward to his human-capital investment (the schooling years accumulated at time  $s$ ). Note that considering the minimum wage at time  $s$  rather than at time  $s-1$  does not change the argument.

and is, in general, dependent of labor-market experience  $z$ .

Clearly, at the end of the working life, the total return in terms of observed earnings is as follows:

$$(23) \quad \beta(T) = \frac{\partial \ln w_{s+T}}{\partial s} \approx \rho \beta [1 + (1-\rho) + (1-\rho)^2 + (1-\rho)^3 + \dots + (1-\rho)^T].$$

### 3.3 Dynamic return to schooling in terms of net potential earnings

The return in expression (22) is, in general, lower than the return in expression (15), although the first converges to the latter as labor-market experience  $z$  increases. Indeed, for a value of  $\rho \in (0,1)$ , the following expression holds:

$$(24) \quad \beta(\infty) = \lim_{z \rightarrow \infty} \beta(z) \approx \rho \beta \left[ \frac{1}{1-(1-\rho)} \right].$$

Therefore, the dynamic model (14) is able to provide a measure of  $\beta$  comparable<sup>7</sup> with expression (15). We label  $\beta(\infty)$  as dynamic return to schooling in terms of net potential earnings.

Expression (24) helps to show that our interpretation of  $\beta$  in terms of *net potential* rather than *observed* earnings is the most appropriate because nobody can live and work forever. To the extent of  $T$  being a finite number, the return to schooling in terms of observed earnings  $\beta(z)$  can never be equal to  $\beta$ , but in the very special case of  $\rho = 1$ .

### 3.4 Final remarks

It is easy to prove that the following inequalities hold:

$$(25) \quad \beta(0) < \beta(z) < \beta(T) < \beta$$

for every  $z$  and  $T$  such that  $0 < z < T < \infty$  and  $\beta > 0$ , if  $\rho \in (0,1)$ .

In addition, one can verify that:

$$(26) \quad \beta(0) = \beta(z) = \beta(T) = 0 < \beta$$

for every  $z$  and  $T$  such that  $0 < z < T < \infty$  and  $\beta > 0$ , if  $\rho = 0$ .

Finally, it is easy to show that:

$$(27) \quad \beta(0) = \beta(z) = \beta(T) = \beta$$

for every  $z$  and  $T$  such that  $0 < z < T < \infty$  and  $\beta > 0$ , if  $\rho = 1$ .

### 3.5 Numerical example

As a matter of example, we use the adjustment model (14) to compute returns to schooling in terms of both potential and observed earnings using our preferred estimates in Table 1 (GMM-SYS, controlling for year effects).

---

<sup>7</sup>Note that  $\rho \beta \left[ \frac{1}{1-(1-\rho)} \right] = \beta$ .

Using expression (24), it is easy to calculate that the return to schooling in terms of potential earnings  $\beta(\infty)$ , the equivalent of the static  $\beta$  return in the standard Mincer model (11), is equal to 0.053, 0.089 and 0.093 in Denmark, Finland and Belgium, respectively.

In addition, we can use expression (22) to calculate the average return to schooling in terms of observed earnings over the working life  $\beta(z)$ . As shown in Figure 1 (the horizontal axis measures potential labor-market experience  $z$ ), the standard static Mincerian model would not capture the fact that the return to schooling is increasing over time at the beginning of the working life and that the actual return to schooling at labor-market entry  $\beta(0)$  (estimated at 0.031, 0.062 and 0.070 in Denmark, Belgium and Finland, respectively) may be well below the potential one ( $\beta(\infty)$ ).

Since a dynamic version of the Mincer equation seems sufficiently robust on the empirical ground, the next step consists of discussing its possible theoretical foundations. Specifically, the next section shows that a dynamic Mincer equation can be obtained as the solution of a simple wage-bargaining model.

#### 4. Bargaining model

From a theoretical point of view, assumption (10) fits within the perfect-competition framework where the nominal wage equals the monetary value of the marginal labor productivity. However, if one believes that the imperfect-competition framework is a more realistic view of the labor market<sup>8</sup>, then *several* arguments can support the statement that assumption (10) is unlikely to hold. This section focuses on *one* of the possible arguments: the existence of wage bargaining at worker-employer level. Additional arguments (asymmetric information, role of unions and efficiency wages) are briefly discussed in the last section of this paper.

The standard Mincerian model puts emphasis on the supply side: the more an individual invests in his human-capital development, the higher his wage is. The model that is presented in this section aims at enhancing the role played by demand factors in determining wages, without diminishing the one played by supply factors. More explicitly, the argument is that schooling and post-schooling investments provide individuals with *net potential* earnings, meaning skills required to earn a given amount of money. However, *observed* earnings are likely to be the result of both worker's skills (supply) and employer's willingness to pay (demand). Since real-life labor markets are characterized by wage bargaining, the possibility of a margin-formation between observed earnings and net potential earnings should not be ruled out a-priori. This implies that observed earnings may not coincide with net potential earnings at any time, although the former generally depend on the latter.

As additional feature, the model keeps into account the stylized fact that observed earnings exhibit path-dependence (persistence). To the best of our knowledge, this feature is novel because the existing (micro and macro) evidence on the autoregressive nature of observed earnings<sup>9</sup> has not received attention in Mincerian studies so far.

To anticipate the model's conclusion, current observed earnings are shown to be dependent on both past observed earnings and current net potential earnings.

Let us assume that the logarithm of the observed earnings of a worker arises from a simple, decentralized Nash bargaining between a worker and an employer and that:

---

<sup>8</sup> A general reference is the New Keynesian view of the labor market.

<sup>9</sup> See Taylor (1999) for a good survey.

- Worker objective function: the worker maximizes his observed earnings at time  $t^{10}$ , namely the worker maximizes  $U_t^w = \ln w_t$
- Employer objective function: the employer maximizes the difference between the monetary value of the worker's net productivity at time  $t$  and the salary that he has to pay to the worker, namely the employer maximizes  $U_t^e = \ln npe_t - \ln w_t$
- Worker outside option: if bargaining fails, the outside option for the worker depends of whether he is employed or unemployed and, in case he is employed, on whether he bargains with his own employer or not:

Case 1) if the worker is employed at time  $t-1$ , bargains with his own employer at time  $t$  and bargaining fails, then the outside option for the worker at time  $t$  is the unemployment benefit  $b$  at time  $t$ , i.e.  $\tilde{U}_t^w = \ln b_t$

Case 2) if the worker is employed at time  $t-1$ , bargains with an employer different from his own employer at time  $t$  and bargaining fails, then the outside option for the worker at time  $t$  is the salary that he received from his own employer at time  $t-1$  which he continues earning at time  $t$ , i.e.  $\tilde{U}_t^w = \ln w_{t-1}$

Case 3) if the worker is unemployed at time  $t-1$ , bargains with an employer at time  $t$  and bargaining fails, then the outside option for the worker at time  $t$  is the unemployment benefit  $b$  that he received at time  $t-1$  which he continues receiving at time  $t$ , i.e.  $\tilde{U}_t^w = \ln b_{t-1}$

- Employer outside option: if bargaining fails, the outside option for the employer is  $\tilde{U}_t^e = 0$  because the employer neither gets the monetary value of the worker's net productivity nor pays a salary
- Nash bargaining function: the Nash bargaining function has a Cobb-Douglas specification, i.e.  $U_t = (U_t^w - \tilde{U}_t^w)^\rho (U_t^e - \tilde{U}_t^e)^{1-\rho}$

As usual in the literature, the coefficient  $\rho \in [0,1]$  in the Nash bargaining function is interpreted as the bargaining power of the worker, while  $1-\rho$  is the bargaining power of the employer. The reason why the bargaining power of the worker is labeled in the same way as the speed of adjustment is clarified at the end of this section.

The level of the unemployment benefit of an individual usually depends on the whole wage history of the individual. For sake of simplicity, we assume that the unemployment benefit is a simple linear function of the worker's wage history starting from time  $s$  (labor-market entry), that is:

- $\ln b_t = \theta_1 \ln w_{t-1} + \theta_2 \ln w_{t-2} + \dots + \theta_{t-s} \ln w_s$

Under this assumption, it is easy to see that assuming the following outside option for the worker:

---

<sup>10</sup> Note that both observed and net potential earnings must be measured in logarithms to be consistent with the Mincerian assumption (10).

- $\tilde{U}_t^w = \theta_1 \ln w_{t-1} + \theta_2 \ln w_{t-2} + \dots + \theta_{t-s} \ln w_s$

takes into account all the three cases described above. Case 1) is trivially included. Case 2) holds when  $\theta_1 = 1$  and  $\theta_i = 0$  for  $i = 2, \dots, t-s$ . Case 3) holds when  $\theta_1 = 0$  and  $\theta_i \neq 0$  for  $i = 2, \dots, t-s$ .

The solution of the worker-employer bargaining problem provides the following first-order condition:

$$(28) \quad \frac{\rho}{\ln w_t - \theta_1 \ln w_{t-1} - \theta_2 \ln w_{t-2} - \dots - \theta_{t-s} \ln w_s} = \frac{1-\rho}{\ln npe_t - \ln w_t}$$

which, in turn, yields:

$$(29) \quad \ln w_t = (1-\rho)\theta_1 \ln w_{t-1} + (1-\rho)\theta_2 \ln w_{t-2} + \dots + (1-\rho)\theta_{t-s} \ln w_s + \rho \ln npe_t$$

Hence, if the worker has full bargaining power ( $\rho = 1$ ), then expression (29) becomes expression (10) and the standard Mincerian model holds. Intuitively, only when the worker has full bargaining power, he is actually able to earn all his net potential earnings. In this case, the employer is indifferent between employing and not employing because  $U_t^e = \tilde{U}_t^e = 0$ .

On the other hand, if the worker has zero bargaining power ( $\rho = 0$ ), then expression (29) implies  $\ln w_t = \theta_1 \ln w_{t-1} + \theta_2 \ln w_{t-2} + \dots + \theta_{t-s} \ln w_s$ . In this case, the worker is indifferent between working and being unemployed because  $U_t^w = \tilde{U}_t^w$ .

In general, when the bargaining power of the worker is neither null nor full ( $0 < \rho < 1$ ), replacing expression (9) into (29) yields:

$$(30) \quad \ln w_t \approx (1-\rho)\theta_1 \ln w_{t-1} + (1-\rho)\theta_2 \ln w_{t-2} + \dots + (1-\rho)\theta_{t-s} \ln w_s + \rho(\alpha + \beta s + \delta z + \phi z^2)$$

or alternatively:

$$(31) \quad \ln w_t \approx \upsilon_0 + (1-\rho)\theta_1 \ln w_{t-1} + (1-\rho)\theta_2 \ln w_{t-2} + \dots + (1-\rho)\theta_{t-s} \ln w_s + \upsilon_2 s + \upsilon_3 z + \upsilon_4 z^2$$

where the all the  $\upsilon$  coefficients are those defined in section 2.

Note that, under case 2) hypotheses i.e.  $\theta_1 = 1$  and  $\theta_i = 0$  for  $i = 2, \dots, t-s$ , model (31) and model (14) perfectly match. Therefore, in case 2), the bargaining power of the worker can be interpreted as a proxy of the speed of adjustment and vice-versa. Specifically, the fact that the speed is far from being one indicates that the bargaining power of the worker is far from being full and vice-versa.

Model (31), as it is, cannot be estimated with usually available panel data because it requires information about the whole wage history of each individual in the dataset, typically not available. However, standard longitudinal datasets usually allow to test for the significance of wage lags up to a certain point in the past. Using our dataset, we are able to test several possibilities and find that the most appropriate specification of model (31) for Belgium and Finland has two significant wage lags while, for Denmark, it has just one lagged wage. Additional wage lags are not statistically significant.

An important issue to be taken into account before estimating model (31) is that the model can only be applied to countries where unemployment benefits are actually paid and cover a large share of the working force. To this respect, we would like to stress

that Boeri and van Ours (2008, p. 283) indicate Belgium, Finland and Denmark as the countries with the highest generosity index of unemployment benefit adjusted for coverage in a sample of 12 European countries. Besides issues of data availability with other countries, the latter is the main reason why these three countries have been chosen for the empirical analysis in this paper.

Note that the number of relevant wage lags (also called wage persistence) may depend on the specific way the unemployment-benefit policies are designed in a given country (duration, eligibility, administrative rules regarding the determination of the benefit level, and so on). As a matter of example, it may be the case that i) recent earnings are relatively more important than older earnings for the determination of the benefit level, or that ii) just the most recent wages really matter for the benefit. This would imply that some of the  $\theta$  coefficients in the simple benefit-determination rule assumed in the bargaining model may be either i) not statistically different from zero or ii) zero by assumption. For instance, if  $\theta_i = 0$  for  $i = 3, \dots, t-s$ , then model (31) would just have two relevant lagged wages.

In addition, the number of relevant wage lags may also depend on the proportion of case 1), case 2) and case 3) workers in the dataset. For instance, if just case 2) workers were in the dataset, model (31) would suggest that just one lag of the hourly wage should be significant because the outside option of the worker would just be that of case 2). The significance of more than one lag may be seen as indication that case 1) and case 3) workers are significantly represented in the dataset.

Of course, many other country-level aspects related to labor-market institutions and legislation may also explain different degrees of wage persistence. For instance, if the share of temporary contracts relative to permanent contracts is higher in country A relative to country B, this may imply a higher number of bargaining processes among workers and employers taking place in country A and may affect the persistence of wages in country A relative to B. Alternatively, if firing is more costly or difficult in country B, this would imply a different outside option of the worker in country B relative to A and may affect the relative degree of wage persistence in the two countries. Table 2 presents our GMM-SYS estimates based on model (31), controlling for endogeneity, individual heterogeneity and year effects. All standard tests are passed and their results indicate a specification improvement for Belgium, no real gain with respect to the adjustment model for Denmark, some mixed evidence for Finland where the second wage lag is significant but the Hansen J test does not significantly improve and the 2<sup>nd</sup> order autocorrelation test shows a lower p-value.

The main conclusion is that a micro-founded dynamic wage model, the bargaining model, can fit the data better than a simple adjustment model but requires more (sometimes non-testable) theoretical assumptions.

## 5. Conclusions

The main conclusions of this paper are the following:

- a. The equality between the observed wage of an individual and the monetary value of his net human-capital productivity (the so-called net potential wage), assumed by the standard Mincerian model, is rejected by the ECHP data for Belgium, Denmark and Finland
- b. A dynamic approach to the Mincer equation based on a simple wage adjustment model implies that the return to schooling in terms of observed earnings is not independent of labor-market experience

- c. The return to schooling in terms of net potential earnings, provided by the standard Mincer equation, can also be computed using a dynamic wage adjustment model
- d. A dynamic adjustment model allows the estimation of the average return to schooling at labor-market entry
- e. A dynamic wage equation can be seen as the solution of a simple wage bargaining model where the role played by demand factors is enhanced with respect to the standard supply-side Mincerian framework
- f. A micro-founded dynamic wage model, the bargaining model, can fit the data better than a simple adjustment model but requires more theoretical assumptions

The rest of this section discusses the above results in the light of the existing literature on human-capital wage equations, with special emphasis on result b. which we consider the most important (although it is a consequence of result a.)

The seminal book by Mincer (1974) has been the starting point of a large body of literature dealing with the estimation of a wage equation where the logarithm of the hourly wage of an individual is explained by his schooling years, potential labor-market experience, and experience squared. Within this framework, the coefficient of schooling years is usually interpreted as being the return to an additional year of schooling in terms of *observed* earnings.

An excellent synthesis of the research papers adopting the Mincer equation as underlying framework has been provided by Card (1999). The reviewed works generally focused on the estimation of the *average* impact of schooling on earnings, by means of both OLS and instrumental-variable techniques.

Today, ‘the state of the art’ described by Card looks outdated. This is partly because the last decade was characterized by a special interest in adopting the Mincer equation for identifying the effect of schooling not only on the mean but also on the *shape* of the conditional wage distribution, using the quantile-regression techniques due to Koenker and Bassett (1978). Starting from a seminal work by Buchinsky (1994), the last few years saw the publication of numerous estimates of the schooling coefficient along the conditional wage distribution, with the frequent finding that education has a positive impact on within-groups wage inequality, as suggested by Martins and Pereira (2004) among others. Additional results using instrumental-variable techniques for quantile regression have been provided by Arias et al. (2001), Chernozhukov and Hansen (2006), Lee (2007), Andini (2008), and many others.

In spite of its wide acceptance within the profession, the spread of the framework developed by Mincer over the last forty years has not been uncontroversial. Some authors criticized the Mincerian framework by arguing that the framework is not able to provide a good fit of empirical data; some stressed that the average effect of schooling on earnings is likely to be non-linear in schooling; some suggested that education levels should replace schooling years in the wage equation. For instance, Murphy and Welch (1990) maintained that the standard Mincer equation provides a very poor approximation of the true empirical relationship between earnings and experience, while Trostel (2005) argued that the average impact of an additional year of schooling on earnings varies with the number of completed schooling years.

In summary, there have been some critical voices but, looking at the big picture, we must reasonably conclude that the history of human-capital regressions has been characterized by a generalized attempt of *consistently* estimating the coefficient of

schooling (both on average and along the conditional wage distribution), under an implicit acceptance of the theoretical interpretation of the schooling coefficient itself. Nevertheless, the important issue of the theoretical interpretation of the schooling coefficient has been recently rediscovered by Heckman et al. (2005), who empirically tested several implications of the classical Mincerian framework, using Census data for the United States. Among other implications of the Mincerian approach, the authors tested and often rejected the implication that the return to schooling in terms of observed earnings is *independent* of labor-market experience.

On the lines of Heckman et al. (2005), our paper has provided additional theoretical and empirical arguments against the usual interpretation of the coefficient of schooling in the standard Mincer equation. Indeed, we have argued that the return to schooling in terms of observed earnings is, in general, *dependent* of labor-market experience (result b.). This result is also consistent with more recent empirical evidence provided Belzil (2007) and with some earlier evidence presented by Andini (2005)<sup>11</sup>.

As shown, the result b. can be easily derived from a dynamic specification of the Mincer equation where past observed earnings contribute to explain current observed earnings. This specification is strongly supported by the ECHP data for three European countries, once endogeneity, individual heterogeneity and time effects are accounted for (result a.), and allows to compute the return to schooling at labor-market entry (result d.) as well as the standard Mincerian return to schooling (result c.).

This paper also provides a theoretical micro-foundation of a dynamic Mincer equation, where demand factors are considered as important as supply factors for wage determination (result e.). It is worth stressing that, of course, we do not claim for generality. Clearly, the bargaining model in section 4 holds under a set of specific assumptions. The main issue, at this point, is whether these assumptions bring us closer to reality (enhanced role of demand factors in determining wages) or not. The bargaining model is presented here as a micro-founded alternative to the simple adjustment model. The former can perform better than the latter in terms of data fitting because it allows for more than one wage lag but it is based on more theoretical hypotheses (result f.) and, as it stands, it is only suitable to be used for countries where unemployment benefits are actually paid and cover a large share of the working force.

Summing up, to really conclude this paper, we would like to stress that there seems to be substantial empirical evidence supporting the argument that past observed earnings, *together with* accumulated human capital (schooling and post-schooling investments), play an important role in explaining current observed earnings. This finding should open the door to new research efforts looking for alternative, and perhaps more general, theoretical foundations of a *dynamic* Mincer equation. Issues related to asymmetric information (for instance, the case where the employer does not observe the net potential earnings of the worker), role of unions (wage bargaining at collective level and insider-outsider considerations) and efficiency wages (the employer cannot observe the worker's effort) are interesting topics for future investigation.

---

<sup>11</sup> Some of the ideas that are presented in this paper can also be found in Andini (2007), Andini (2009) and Andini (forthcoming). However, these works do not control for endogeneity, individual heterogeneity and time effects in the estimation of the dynamic Mincer equation.

## Appendix. Sample descriptive statistics

Our data are extracted from the European Community Household Panel. We focus on male workers aged between 18 and 65. In order to derive the variables for schooling years (ys), potential labour-market experience (plme) and the logarithm of the gross hourly wage (lnw), we use the following ECHP variables:

- pt023. Age when the highest level of general or higher education was completed
- pe039. How old were you when you began your working life, that is, started your first job or business?
- pd003. Age
- pi211mg. Current wage and salary earnings – gross (monthly)
- pe005. Total number of hours per week (in main + additional jobs)

Specifically, to be consistent with the standard Mincerian model (the representative agent first stops schooling and then starts working), we select a sample of individuals whose age at the completion of the highest level of education was lower than their age at the start of the working life ( $pt023 \leq pe039$ ) and define the above-referred variables as follows:

- $ys = pt023 - 6$  (def. 1)
- $plme = pd003 - ys - 6$  (def. 2)

It is worth stressing that ys numbers do not necessarily reflect successfully completed years of schooling. This is a compromise that allows us to obtain homogenous measures of schooling years (and potential labour-market experience) across three countries that are different in many aspects including educational systems.

The variable lnw represents the natural logarithm of the individual gross hourly wage. From the gross monthly wage (pi211mg), we obtain the daily (dividing the monthly wage by 30) and the weekly wage (multiplying the daily wage by 7). Dividing the latter by the number of weekly hours of work (pe005), we obtain the hourly wage.

### Belgium, 1994-2001

Variable	Obs.	Mean	Std. Dev.	Min	Max
lnw	6873	6.164	0.433	2.815	8.697
